ABSTRACT

We study the population of satellite galaxies formed in a suite of N-body/gasdynamical simulations of galaxy formation in a Λ CDM universe. The simulations resolve the ~ 10 most luminous satellites around each host, and probe systems up to six or seven magnitudes fainter than the primary. We find little spatial or kinematic bias between the dark matter and the satellite population. The radius containing half of all satellites is comparable to the half-mass radius of the dark matter component, and the velocity dispersion of the satellites is a good indicator of the virial velocity of the halo; $\sigma_{\text{sat}}/V_{\text{vir}} \sim 0.9 \pm 0.2$. Applied to the Local Group, this result suggests that the virial velocity of the Milky Way and M31 might be substantially lower than the rotation speed of their disk components; we find $V_{\text{vir}}^{\text{MW}} \sim 109 \pm 22$ km/s and $V_{\text{vir}}^{\text{M31}} \sim 138 \pm 35$ km/s, respectively, compared with $V_{\text{rot}}^{\text{MW}} \sim 220$ km/s and $V_{\text{rot}}^{\text{M31}} \sim 260$ km/s. Although the uncertainties are large, it is intriguing that both estimates are significantly lower than expected from some semianalytic models, which predict a smaller difference between V_{vir} and V_{rot} . The detailed kinematics of simulated satellites and dark matter are also in good agreement: both components show a steadily decreasing velocity dispersion profile and a mild radial anisotropy in their velocity distribution. By contrast, the stellar halo of the simulated galaxies, which consists predominantly of stellar debris from *disrupted* satellites, is kinematically and spatially distinct from the population of *surviving* satellites. This is because the survival of a satellite as a self-bound entity depends sensitively on mass and on time of accretion; surviving satellites are significantly biased toward low-mass systems that have been recently accreted by the galaxy. Our results support recent proposals for the origin of the systematic differences between stars in the Galactic halo and in Galactic satellites: the elusive “building blocks” of the Milky Way stellar halo were on average more massive, and were accreted (and disrupted) earlier than the population of dwarfs that has survived self-bound until the present.

Key words: galaxies: haloes - galaxies: formation - galaxies: evolution.

1 INTRODUCTION

The satellite companions of bright galaxies are exceptionally useful probes of the process of galaxy formation. Studies of the dynamics of satellites around bright galaxies, for example, have provided incontrovertible evidence for the ubiquitous presence of massive dark halos surrounding luminous galaxies, a cornerstone of the present galaxy formation paradigm. Following the pioneering work of Holmberg (1969); Zaritsky et al. (1993, 1997) compiled perhaps the first statistically-sound sample of satellite-primary systems with

accurate kinematics, and were able to provide persuasive evidence that the dark matter halos hinted at by the flat rotation curves of spiral galaxies (Sofue & Rubin 2001 and references therein) truly dwarf the mass of the luminous component and extend well beyond the luminous radius of the central galaxy.

Satellite dynamical studies have entered a new realm since the advent of large redshift surveys, such as the 2dFGRS (Colless et al. 2001) and the SDSS (York et al. 2000; Strauss et al. 2002), which have increased many-fold the number of primary-satellite systems known. Recent work based on these datasets have corroborated and extended the results of Zaritsky et al, and their conclusions now appear secure. The dynamics of satellites confirm (i) that dark matter

* Fellow of the Canadian Institute for Advanced Research.

halos extend to large radii, (ii) that more massive halos surround brighter galaxies, and (iii) that early-type galaxies are surrounded by halos about twice as massive as late-type systems of similar luminosity (McKay et al. 2002; Prada et al. 2003; Brainerd 2004b; van den Bosch et al. 2005; see Brainerd 2004a for a recent review).

Satellites may also be thought of as probes of the faint end of the luminosity function. After all, satellite galaxies are, by definition, dwarf systems, thought to be themselves surrounded by their own low-mass dark matter halos. These low-mass halos are expected to be the sites where the astrophysical processes that regulate galaxy formation (i.e., feedback) operate at maximum efficiency. Thus, the internal structure, star formation history, and chemical enrichment of satellites provide important constraints on the process of galaxy formation in systems where theoretical models predict a highly non-trivial relation between dark mass and luminosity (see, e.g., White & Rees 1978; Kauffmann et al. 1993; Cole et al. 1994; see as well Cole et al. 2000 and Benson et al. 2002 for a more detailed list of references).

The anticipated highly non-linear mapping between dark matter and light at the faint-end of the luminosity function is perhaps best appreciated in the satellite population of the Local Group, where the relatively few known satellites stand in contrast with the *hundreds* of “substructure” cold dark matter (CDM) halos of comparable mass found in cosmological N-body simulations (Klypin et al. 1999; Moore et al. 1999). Possible resolutions of this “satellite crisis” have been discussed by a number of authors, and there is reasonably broad consensus that it originates from inefficiencies in star formation caused by the combined effects of energetic feedback from evolving stars and by the diminished supply of cold gas due to reionization (see, e.g. Kauffmann et al. 1993; Bullock et al. 2000; Somerville et al. 2001; Benson et al. 2002). These effects combine to reduce dramatically the star formation activity in substructure halos, and can reconcile, under plausible assumptions, the substructure halo mass function with the faint end of the satellite luminosity function (Stoehr et al. 2002; Kazantzidis et al. 2004; Penarrubia et al. 2007).

The price paid for reconciling cold dark matter substructure with the Local Group satellite population is one of simplicity, as the “feedback” processes invoked involve complex astrophysics that is not yet well understood nor constrained. It is not yet clear, for example, whether the brighter satellites inhabit the more massive substructures, or whether, in fact, there is even a monotonic relation between light and mass amongst satellites. This issue is further complicated by the possibility that a substantial fraction of a satellite’s mass may have been lost to tides. Tidal stripping is expected to affect stars and dark matter differently, complicating further the detailed relation between light and mass in substructure halos (Hayashi et al. 2003; Kravtsov et al. 2004; Strigari et al. 2007a,b).

These uncertainties hinder as well the interpretation of satellites as relics of the hierarchical galaxy assembly process, and consensus has yet to emerge regarding the severity of the biases that the various effects mentioned above may engender. Do the spatial distribution of satellites follow the dark matter? Is the kinematics of the satellite population substantially biased relative to the dark matter’s? Have satellites lost a substantial fraction of their stars/dark matter to stripping? Are surviving satellites fair tracers of the population of accreted dwarfs?

Of particular interest is whether satellites may be considered relics of the “building blocks” that coalesced to form the early Galaxy. Indeed, the stellar halo of the Milky Way is regarded, in hierarchical models, to consist of the overlap of the debris of many

accreted satellites which have now merged and mixed to form a kinematically hot, monolithic stellar spheroid (Searle & Zinn 1978; Bullock & Johnston 2005; Abadi et al. 2006; Moore et al. 2006). A challenge to this view comes from detailed observation of stellar abundance patterns in satellite galaxies in the vicinity of the Milky Way. At given metallicity, the stellar halo (at least as sampled by stars in the solar neighbourhood) is systematically more enriched in α -elements than stars in Galactic satellites (Fuhrmann 1998; Shetrone et al. 2001, 2003; Venn et al. 2004), a result that remains true even when attempting to match stars of various ages or metallicities (Unavane et al. 1996; Gilmore & Wyse 1998; Pritzl et al. 2005). Can hierarchical models explain why satellites identified today around the Milky Way differ from the ones that fused to form the Galactic halo?

Preliminary clues to these questions have been provided by the semianalytic approach of Bullock, Johnston and collaborators (Bullock & Johnston 2005; Font et al. 2006a,b), who argue that hierarchical models predict naturally well-defined distinctions between the halo and satellite stellar populations. Detailed answers, however, depend critically on which and when substructure halos are “lit up” and how they evolve within “live” dark matter halos. These are perhaps best addressed with direct numerical simulation that incorporates the proper cosmological context of accretion as well as the gasdynamical effects of cooling and star formation in an evolving population of dark matter halos. The study we present here aims to address these issues by analyzing the properties of the satellite population of L_* galaxies simulated in the Λ CDM scenario. We introduce briefly the simulations in § 2, analyze and discuss them in § 3 and we conclude with a summary in § 4.

2 THE NUMERICAL SIMULATIONS

Our suite of eight simulations of the formation of L_* galaxies in the Λ CDM scenario is the same discussed recently by Abadi, Navarro and Steinmetz 2006. The simulations are similar to the one originally presented by Steinmetz & Navarro (2002), and have been analyzed in detail in several recent papers, which the interested reader may wish to consult for details on the numerical setup (Abadi et al. 2003a,b; Meza et al. 2003, 2005; Navarro et al. 2004).

Briefly, each simulation follows the evolution of a small region of the universe chosen so as to encompass the mass of an L_* galaxy system. This region is chosen from a large periodic box and resimulated at higher resolution preserving the tidal fields from the whole box. The simulation includes the gravitational effects of dark matter, gas and stars, and follows the hydrodynamical evolution of the gaseous component using the Smooth Particle Hydrodynamics (SPH) technique (Steinmetz 1996). We adopt the following cosmological parameters for the Λ CDM scenario: $H_0 = 65$ km/s/Mpc, $\sigma_8 = 0.9$, $\Omega_\Lambda = 0.7$, $\Omega_{\text{CDM}} = 0.255$, $\Omega_{\text{bar}} = 0.045$, with no tilt in the primordial power spectrum.

All simulations start at redshift $z_{\text{init}} = 50$, have force resolution of order 1 kpc, and the mass resolution is chosen so that each galaxy is represented on average, at $z = 0$, with $\sim 50,000$ gas/dark matter particles and $\sim 125,000$ star particles. Each resimulation follows a single $\sim L_*$ galaxy in detail, and resolves a number of smaller, self-bound systems we shall call generically “satellites”. We shall hereafter refer to the main galaxy indistinctly as “primary” or “host”.

Gas is allowed to turn into stars at rates consistent with the empirical Schmidt-like law of Kennicutt (1998) in collapsed regions at the center of dark matter halos. Because star formation

Figure 1. Spatial distribution of the stellar component of four of our simulated galaxies at $z=0$. Each panel corresponds to a different simulation, projected so that the inner galaxy is seen approximately “edge-on”. The virial radius of the system is marked by the outer green circle in each panel. The inner circle has a radius of 20 kpc, where most the stars in each galaxy are found. Stars that have formed in satellites that survive as self-bound entities until $z = 0$ are shown in yellow. “In situ” stars, i.e., those formed in the most massive progenitor of the galaxy, are shown in cyan, whereas those formed in satellites that have been accreted and disrupted by the main galaxy are shown in red. Note that the diffuse outer stellar halo reaches almost out to the virial radius, and consists almost exclusively of accreted stars. The inner galaxy, on the other hand, is dominated by stars formed “in situ”.

proceeds efficiently only in high-density regions, the stellar components of primary and satellites are strongly segregated spatially from the dark matter. We include the energetic feedback of evolving stars, although its implementation mainly as a heating term on the (dense) gas surrounding regions of active star formation implies that most of this energy is lost to radiation and that feedback is ineffective at curtailing star formation. The transformation of gas into

stars thus tracks closely the rate at which gas cools and condenses at the center of dark matter halos. This results in an early onset of star-forming activity in the many progenitors of the galaxy that collapse at high redshift, as well as in many of the satellite systems we analyze here.

Another consequence of our inefficient feedback algorithm is that gas cooling and, therefore, star formation, proceed with simi-

lar efficiency in all well-resolved dark matter halos, irrespective of their mass. As a result, the total stellar mass of a satellite correlates quite well with the “original” mass of its progenitor dark halo; i.e., the total mass of the satellite before its accretion into the virial radius of its host. We define the *virial* radius, r_{vir} , of a system as the radius of a sphere of mean density $\Delta_{\text{vir}}(z)$ times the critical density for closure. This definition defines implicitly the virial mass, M_{vir} , as that enclosed within r_{vir} , and the virial velocity, V_{vir} , as the circular velocity measured at r_{vir} . Quantities characterizing a system will be measured within r_{vir} , unless otherwise specified. The virial density contrast, $\Delta_{\text{vir}}(z)$ is given by $\Delta_{\text{vir}}(z) = 18\pi^2 + 82f(z) - 39f(z)^2$, where $f(z) = [\Omega_0(1+z)^3/(\Omega_0(1+z)^3 + \Omega_\Lambda)] - 1$ and $\Omega_0 = \Omega_{\text{CDM}} + \Omega_{\text{bar}}$ (Bryan & Norman 1998). $\Delta_{\text{vir}} \sim 100$ at $z = 0$.

It is likely that improvements to our feedback algorithms may lead to revisions in the efficiency and timing of star formation in these galaxies, and especially in the satellites, but we think our results will nonetheless apply provided that these revisions do not compromise the relatively simple relation between stellar mass and halo mass that underpins many of our results. For example, we expect that modifications of the star formation algorithm will affect principally the number, age, and chemical composition of stars, rather than the dynamical properties of the satellites. This is because the latter depend mainly on the mass, orbit, and timing of the merging progenitors, which are largely dictated by the assumed cosmological model. These properties are less sensitive to the complex astrophysics of star formation and feedback, and therefore our analysis focuses on the kinematics and dynamical evolution of the satellite population around the eight galaxies in our simulation suite.

3 RESULTS AND DISCUSSION

3.1 Characterization of the satellite population

Figure 1 shows the spatial distribution of all star particles in four of our simulated galaxies. Stars are assigned to one of three components and colored accordingly. Particles in cyan are “in-situ” stars; i.e., stars that formed in the main progenitor of the primary galaxy. Stars in red formed in satellites that have since been accreted and fully disrupted by the tidal field of the galaxy. Stars in yellow formed in systems that survive as recognizable self-bound satellites until $z = 0$. As discussed in detail by Abadi et al (2006), the tidal debris of fully disrupted satellites makes up the majority of the smooth outer stellar halo component. “In-situ” stars, on the other hand, dominate the inner galaxy, whereas surviving satellites are easily identifiable as overdense, tightly bound clumps of stars.

In practice, we identify satellite systems using a friends-of-friends algorithm to construct a list of potential stellar groupings, each of which is checked to make sure that (i) they are self-bound, and that (ii) they contain at least 35 star particles. This minimum number of stars (which corresponds roughly to $\sim 0.03\%$ of the stellar mass of the primary at $z = 0$) is enough to ensure the reliable identification of the satellite at various times and the robust measurement of their orbital properties, but is insufficient to study the internal structure of the satellite. The satellite identification procedure is run for all snapshots stored for our simulations, allowing us to track the evolution of individual satellites.

Figure 2. Cumulative luminosity distribution of simulated satellites (filled circles), averaged over our eight simulations, and compared with the Milky Way (blue dashed line) and M31 (red dotted curve) satellite systems. Satellite luminosities are scaled to the luminosity of the host. Error bars indicate Poisson uncertainties in the computation of the average. The flattening of the simulated satellite distribution below 0.1% of the primary luminosity is due to numerical limitations. The Local Group data are taken from van den Bergh (1999). For the MW and M31 systems we include only satellites at distances closer than 300 kpc from the central galaxy.

With these constraints, our simulations resolve, at $z = 0$, an average of about 10 satellites within the virial radius of each simulated galaxy. The cumulative luminosity distribution of these satellites (computed in the V band¹ for ease of comparison with data available for the Local Group satellites) is shown in Figure 2. The brightest satellite is, on average, about $\sim 12\%$ as bright as the primary, in reasonable agreement with the most luminous satellite around the Milky Way and M31: the LMC and M33 are, respectively, 11% and 8% as bright as the MW and M31 (van den Bergh 1999).

At brightnesses below 0.2% of L_{host} the number of simulated satellites levels off as a result of numerical limitations. Independent tests (Abadi et al, in preparation) show that this brightness limit corresponds to where satellite identification in the simulations becomes severely incomplete. We note that this limitation precludes us from addressing the “satellite crisis” alluded to in §1: our simulations lack the numerical resolution needed to resolve the hundreds of low-mass substructure halos found in higher-resolution CDM simulations. On average, the 10th brightest satellite in our simulations is ~ 5.6 mag fainter than the primary; for comparison, the MW and M31 have only 2 and 5 satellites as bright as that.

Given the small number of systems involved and the considerable scatter from simulation to simulation (the number of bright satellites ranges from 4 to 21 in our eight simulations) we conclude

¹ Luminosity estimates in various bands are made by convolving the masses and ages of star particles with standard spectrophotometric models, see, e.g., Abadi et al 2006 for details.

Figure 3. Number density profile of simulated satellites, after scaling their positions to the virial radius of each host and stacking all eight simulations (solid circles; error bars denote Poisson uncertainties associated with the total number of satellites in each radial bin). The dotted line corresponds to the average dark matter density profile, and the dashed line to the stars in the outer stellar halo. The vertical normalization for the satellite and stellar halo profiles has been chosen so that all profiles approximately coincide at $r \sim 0.15 r_{\text{vir}}$. Note that the spatial distribution of satellites is similar to the dark matter, and that stars in the stellar halo are significantly more centrally concentrated. Arrows mark the radius containing half the objects in each component. See text for further discussion.

that there is no dramatic discrepancy between observations and simulations at the bright end of the satellite luminosity function. Applying our results to the full Local Group satellite population, including, in particular, the extremely faint dwarfs being discovered by panoramic surveys of M31 and by the SDSS (Zucker et al. 2004, 2006; Willman et al. 2005; Martin et al. 2006; Belokurov et al. 2006, 2007; Irwin et al. 2007; Majewski et al. 2007, Ibata et al. 2007 submitted), involves a fairly large extrapolation, and should be undertaken with caution (see, e.g., Peñarrubia, McConnachie & Navarro 2007 for a recent discussion).

3.2 Spatial distribution

Figure 1 shows that satellites are found throughout the virial radius of the host and that, unlike stars in the smooth stellar halo, satellites show little obvious preference for clustering in the vicinity of the central galaxy. This is confirmed in Figure 3, where the solid circles show the number density profile of satellites, after rescaling their positions to the virial radius of each host and stacking all eight simulations. The dashed and dotted lines in this figure correspond, respectively, to the density profile of the stellar and dark matter halos, scaled and stacked in a similar way. The vertical normalization of the satellite and stellar halo profiles is arbitrary, and has been chosen so that all profiles approximately match at $r \sim 0.15 r_{\text{vir}}$.

There is little difference in the shape of the dark matter

Figure 4. Spherical components of satellite velocities at $z = 0$ as a function of their distance to the center of the host galaxy. Each system has been rotated so that the angular momentum of the inner galaxy is aligned with the direction of the z -coordinate axis. Positions and velocities have been scaled to the virial radius and velocity of each host halo. Panels on the right show the velocity distributions of the satellite population within r_{vir} (solid lines) and compare it to the dark matter particles (dotted lines). The velocity dispersions are given in each panel. Note the slight asymmetry in the satellites' V_ϕ velocity distribution, which results from the net co-rotation of satellites around the primary.

and satellite profiles: half of the satellites are contained within $\sim 0.37 r_{\text{vir}}$, a radius similar to the half-mass radius of the dark matter, $\sim 0.3 r_{\text{vir}}$. We conclude that, within the uncertainties, the satellites follow the dark matter. The stellar halo, on the other hand, is much more centrally concentrated than the dark matter and satellites; its half-mass radius is only $\sim 0.05 r_{\text{vir}}$, as shown by the arrows in Figure 3.

This result implies that the spatial distribution of simulated satellites is distinct from that of CDM substructure halos, whose density profile is known to be significantly shallower than the dark matter's (Ghigna et al. 1998, 2000; Gao et al. 2004; Diemand et al. 2004). This suggests that the “mapping” between dark and luminous substructure is highly non-trivial, as argued by Springel et al. (2001) and De Lucia et al. (2004). Our results, which are based on direct numerical simulation, validate these arguments and illustrate the complex relation between galaxies and the subhalos in which they may reside (see also Kravtsov et al. 2004; Nagai & Kravtsov 2005; Gnedin et al. 2006; Weinberg et al. 2006; Libeskind et al. 2007). Luminous satellites are resilient to disruption by tides, and they can survive as self-bound entities closer to the primary, where substructures in dark matter-only simulations may quickly disrupt, as first pointed out by White & Rees (1978).

We conclude that using dark matter substructures to trace directly the properties of luminous satellites is likely to incur substantial and subtle biases which may be difficult to avoid. Models that attempt to follow the evolution of dark matter substructures and their luminous components are likely to fare better (see, e.g. Croton et al. 2006; Bower et al. 2006). At the low mass end, the inclusion of some treatment of the substructure mass loss and tidal

Figure 5. *Top panel:* Radial and tangential velocity dispersion profiles of satellites, dark matter, and stellar halo, computed after scaling to virial values and stacking all simulations in our series. *Bottom panel:* Anisotropy parameter as a function of radius for the satellite population, compared with dark matter particles and with the stellar halo. Note that satellites are only slightly more radially anisotropic than the dark matter and kinematically distinct from the stellar halo.

shocks is needed to put in better agreement semianalytic models with the results from numerical simulations (Taylor & Babul 2001; Benson et al. 2002). Definitive conclusions will probably need to wait until realistic simulations with enhanced numerical resolution and improved treatment of star formation become available.

3.3 Kinematics

The likeness in the spatial distribution of satellites and dark matter anticipates a similar result for their kinematics. This is illustrated in Figure 4, where the panels on the left show the spherical components of the satellites' velocities (in the rest frame of the host and scaled to its virial velocity) versus galactocentric distance (in units of the virial radius of the host). Velocity components are computed after rotating each system so that the z -axis (the origin of the polar angle θ) coincides with the rotation axis of the inner galaxy. The corresponding velocity distributions are shown by the thick solid lines in the panels on the right, and compared with those corresponding to the dark matter particles (dotted lines).

The velocity distribution of each component is reasonably symmetric and may be well approximated by a Gaussian, except perhaps for the satellites' V_ϕ -component, which is clearly asymmetric. This is a result of net rotation around the z axis: the satellite population has a tendency to co-rotate with the galaxy's inner body which is more pronounced than the dark matter's. Indeed, we find that on average the specific angular momentum of satellites is $\sim 50\%$ higher than the dark matter, and a factor of ~ 10 higher than the stellar halo. This result likely arises as a consequence of the accretion and survival biases discussed below; surviving satellites accrete late and from large turnaround radii, making them especially susceptible to the tidal torques responsible for spinning up

the galaxy. The overall effect, however, is quite small, and rotation provides a negligible amount of centrifugal support to the satellite population.

The velocity dispersion of both satellites and dark matter particles drops steadily from the center outwards, as shown in Figure 5. The top panel shows that the drop is similar in all components, and that the velocity dispersion decreases from its central value by a factor of ~ 2 at the virial radius. This figure also shows that the velocity distribution is radially anisotropic, and that the anisotropy becomes more pronounced in the outer regions. The trends are again similar for satellites and dark matter, rising slowly with radius and reaching $\beta \sim 0.4$ at the virial radius. (The anisotropy parameter, β , is given by $\beta = 1 - (\sigma_t^2/2\sigma_r^2)$, where σ_r is the radial velocity dispersion and $\sigma_t = \sqrt{(\sigma_\phi^2 + \sigma_\theta^2)/2}$ is the tangential velocity dispersion.)

The stellar halo, on the other hand, is kinematically distinct from the satellites and from the dark matter. Overall, its velocity dispersion is lower, and its anisotropy is more pronounced, rising steeply from the center outwards and becoming extremely anisotropic ($\beta \sim 0.8$) in the outer regions. As discussed in detail by Abadi et al (2006), this reflects the origin of the stellar halo as debris from satellite disruption, which occur at small radii, where tidal forces are maximal. Stars lost during disruption (merging) events and that now populate the outer halo must therefore be on rather eccentric orbits, as witnessed by the prevalence of radial motions in Figure 5. The kinematical distinction between satellites and stellar halo thus suggests that few halo stars have been contributed by stripping of satellites that have survived self-bound until the present. We shall return to this issue below.

3.4 Application to the Local Group

The lack of strong kinematical bias between satellites and dark matter may be used to estimate the virial velocity of the Milky Way and M31. For example, assuming that the radial velocity dispersion of the satellites is related to the virial velocity by $\sigma_r \sim 0.9 (\pm 0.2) V_{\text{vir}}$ (see Figure 4; the uncertainty is just the rms scatter from our eight simulations), we obtain $V_{\text{vir}}^{\text{MW}} \sim 109 \pm 22$ km/s from the ~ 99 km/s Galactocentric radial velocity dispersion of the eleven brightest satellites (see, e.g., the compilation of van den Bergh 1999).

The same procedure may be applied to M31 satellites. Taking into account projection effects, we find that the line-of-sight satellite velocity dispersion is $\sigma_{\text{los}} \sim 0.8 (\pm 0.2) V_{\text{vir}}$. Taking the 16 brightest satellites within 300 kpc from the center of M31, we find $\sigma_{\text{los}} \sim 111$ km/s, implying $V_{\text{vir}}^{\text{M31}} \sim 138 \pm 35$ km/s. We use here the compilation of McConnachie & Irwin (2006), complemented with data for And XIV from Majewski et al. (2007), and for And XII from Chapman et al 2007, submitted).

These results imply that the virial radius of the Milky Way is $r_{\text{vir}}^{\text{MW}} \sim 240$ kpc. Our simulations predict that half of the brightest satellites should be enclosed within ~ 90 kpc, which compares favourably with observations: half of the eleven brightest satellites are within ~ 90.1 kpc from the center of the Milky Way. Contrary to the arguments of Taylor et al. (2005), no substantial bias between satellites and dark matter is required to explain the MW satellite spatial distribution, provided that one accepts a virial radius as small as ~ 240 kpc.

The same argument, applied to M31, suggests that half of the 16 satellites within its virial radius ($r_{\text{vir}}^{\text{M31}} \sim 300$ kpc) must be within ~ 111 kpc, compared with the observational value of ~ 165

Figure 6. *Top panel:* Orbital evolution of two satellites, chosen to illustrate the case of a system that merges quickly with the primary and of another that survives as a self-bound entity until $z = 0$. Curves show the distance from the primary to the self-bound stellar core of the satellite as a function of time. The dotted line shows the evolution of the virial radius of the primary galaxy, and the arrow indicates the time, t_{acc} , when the satellites are first accreted into the primary’s halo. Although both satellites are accreted more or less at the same time, they are not a physical pair and evolve independently. *Bottom panel:* The evolution of the satellites’ bound mass of stars and dark matter, normalized to the values computed at the time of accretion. Note that the stellar component is much more resilient to the effect of tides.

kpc. Note that these radii are actual distances to M31, rather than projections.

Despite the sizable statistical uncertainty inherent to the small number of satellites in these samples, it is interesting that both of the virial velocity estimates mentioned above are significantly lower than the rotation speed measured for these galaxies in the inner regions; $V_{\text{rot}}^{\text{MW}} \sim 220$ km/s and $V_{\text{rot}}^{\text{M31}} \sim 260$ km/s. These low virial velocity estimates are in line with recent work that advocates relatively low masses for the giant spirals in the Local Group (Klypin et al. 2002; Seigar et al. 2006; Abadi et al. 2006; Smith et al. 2006).

If confirmed, this would imply that the circular velocity should drop steadily with radius in the outer regions of these galaxies. As discussed by Abadi et al (2006), this may be the result of “adiabatic contraction” of the dark matter halo following the assembly of the luminous galaxy. However, such result may be difficult to reconcile with semianalytic models of galaxy formation, which favor a better match between V_{rot} and V_{vir} . Croton et al (2006) argue that V_{rot} should be similar to the maximum circular velocity of the dark matter halo, which is only about $\sim 20\%$ larger than V_{vir} for typical concentrations. It is possible that taking into account the effects of the adiabatic contraction and including the self-gravity of the baryon material might induce a large scatter and allow rotation speeds as high as $V_{\text{rot}} \sim 1.5 - 2$ times V_{vir} (A. Benson, private communication). Final word on this issue needs further data to place better constraints on the mass of the halo of the Local Group spirals at large distances, as well as improved semianalytic model-

Figure 7. *Top panel:* Orbital decay timescale of satellites, τ , shown as a function of satellite mass. Decay timescales are computed by fitting an exponential law to the evolution of the apocentric radius of a satellite, and is shown in units of the (radial) orbital period measured at accretion time. Satellite masses (dark+baryons) are scaled to the total mass of the host at t_{acc} . Filled and open circles correspond to satellites that have, respectively, survived or merged with the primary by $z = 0$. Filled squares show the median decay timescale after splitting the sample into equal-number mass bins. More massive satellites spiral in faster due to the effects of dynamical friction. *Bottom panel:* Histogram of surviving and merged satellites as a function of satellite mass. Note the strong mass bias of surviving satellites relative to merged ones.

ing that re-examines critically the response of the dark halo to the formation of the luminous galaxy. At least from the observational point of view, the steady pace of discovery of new satellites of M31 and MW facilitated by digital sky surveys implies that it should be possible to revisit this issue in the near future with much improved statistics.

3.5 Satellite evolution

3.5.1 Merging and survival

Satellites are affected strongly by the tidal field of the primary, and evolve steadily after being accreted into the halo of the host galaxy. This is illustrated in Figure 6, where the upper panel shows the evolution of the galactocentric distance for two satellites in one of our simulations. These two satellites follow independent accretion paths into the halo of the primary galaxy; after initially drifting away from the galaxy due to the universal expansion, they reach a turnaround radius of a few hundred kpc and are then accreted into the virial radius of the primary at similar times, ~ 4.5 Gyr after the Big Bang ($z \sim 1.5$). The accretion is indicated by the intersection between the trajectory of each satellite in the upper panel of Figure 6 and the dotted line, which shows the evolution of the virial radius of the main progenitor of the primary.

Figure 8. *Top panel:* Orbital pericenter-to-apocenter ratio measured at two different times during the evolution of a satellite. Values on the horizontal axis correspond to the time of accretion whereas values on the vertical axis are computed once dynamical friction has eroded the apocentric distance to $\sim e^{-1}$ of its turnaround value. Most satellites lie above the 1:1 dotted line, indicating significant orbital circularization by dynamical friction. Open and filled circles correspond, respectively, to merged or surviving satellites at $z = 0$. Open and filled squares mark the median of each of those populations, respectively. *Bottom panel:* Histogram of pericenter-to-apocenter ratio at the time of accretion for surviving and merged satellites. Note that satellites originally on more eccentric orbits tend to merge faster.

We define the time that the satellite first enters the virial radius of the primary as the *accretion time*, t_{acc} , or z_{acc} , if it is expressed as a redshift. Because masses, radii, and other characteristic properties of a satellite are modified strongly by the tides that operate inside the halo of the primary, it is useful to define the satellite’s properties at the time of accretion, and to refer the evolution to the values measured at that time.

One example of the effect of tides is provided by the self-bound mass of the satellite, whose evolution is shown in the bottom panel of Figure 6. The dark matter that remains bound to the satellite (relative to that measured at accretion time) is shown by open symbols; the bound mass in stars is shown by solid triangles. One of the satellites (dashed lines) sees its orbit eroded quickly by dynamical friction, and merges with the primary less than 4 Gyr after accretion, at which point the self-bound mass of the dark matter and stellar components drops to zero. The orbital period decreases rapidly as the satellite sinks in; we are able to trace almost 5 complete orbits before disruption although, altogether, the satellite takes only 2.5 Gyr to merge after the first pericentric passage, a time comparable to just half the orbital period at accretion time.

As the satellite is dragged inwards by dynamical friction dark matter is lost much more readily than stars; after the first pericentric passage only about 40% of the original dark mass remains attached to the satellite, compared with 85% of the stars. This is a result of the strong spatial segregation between stars and dark matter which results from gas cooling and condensing at the center of dark halos before turning into stars. Stars are only lost in large numbers at the time of merger, when the satellite is fully disrupted by the tides.

The second satellite (solid lines in Figure 6) survives as a self-bound entity until the end of the simulation. Its orbit is affected by dynamical friction, but not as drastically as the merged satellite: after completing 3 orbits, its apocentric distance has only dropped from ~ 250 kpc at turnaround ($t_{\text{ta}} \sim 3$ Gyr) to ~ 180 kpc at $z = 0$. The stars in the satellite survive almost unscathed; more than 85% of stars remain bound to the satellite at the end of the simulation, although only $\sim 45\%$ of the dark matter is still attached to the satellite then.

As expected from simple dynamical friction arguments, the final fate of a satellite regarding merging or survival depends mainly on its mass and on the eccentricity of its orbit. The “merged” satellite in Figure 6 is ~ 6 times more massive than the “surviving” one and is on a much more eccentric orbit: its first pericentric radius is just ~ 20 kpc, compared with 45 kpc for the surviving satellite. More massive satellites on eccentric orbits spiral in faster than low-mass ones, making themselves more vulnerable to tides and full disruption.

This is confirmed in Figure 7, where we show the orbital decay timescale of all satellites identified in our simulations as a function of their mass. Satellite masses are shown in units of the mass of the primary galaxy at the time of accretion, and decay timescales, τ , are normalized to the orbital period of the satellite, measured at the same time. (The timescale τ is computed by fitting the evolution of the apocentric distance of the satellite, a good proxy for the orbital energy, to an exponential law.)

Surviving satellites are shown as filled circles in Figure 7, whereas open circles denote merged satellites. More massive satellites clearly spiral in faster: τ is typically less than an orbital period for a satellite whose mass exceeds $\sim 20\%$ of the primary. On the other hand, decay timescales are often larger than ~ 10 orbital periods for satellites with masses below 1% of the primary. The dotted line shows the $\tau \propto m^{-1}$ relation expected from simple dynamical friction arguments (Binney & Tremaine 1987). Most satellites follow this trend, except perhaps for the most massive systems, but this may just reflect difficulties estimating τ for systems on very rapidly decaying orbits, because of poor time sampling. The main result of these trends is a severe underrepresentation of surviving satellites amongst massive satellites, as shown by the distribution of satellite masses in the bottom panel of Figure 7.

3.5.2 Orbital circularization

As they are dragged inwards by dynamical friction, the orbital energy of the satellites is affected more than its angular momentum and, as a result, the satellites’ orbits become gradually more circular. This is shown in Figure 8, where we plot the ratio between apocentric and pericentric distance, $r_{\text{per}}/r_{\text{apo}}$, at the time of accretion versus the same quantity, but measured after dynamical friction has eroded r_{apo} to e^{-1} of its value at accretion.

As in Figure 7, open and filled circles indicate “merged” and “surviving” satellites at $z = 0$. The vast majority of the points lie above the 1:1 line, indicating that the orbits have become significantly less eccentric with time. Some points lie below the dotted line, indicating the opposite effect; however, most of these cases correspond to complex accretion where the satellite comes as a member of a pair of satellites and is subject to three-body interactions during accretion. (See Sales et al 2007 for further details.)

The large open and filled squares indicate the median

Figure 9. Distribution of satellite stellar masses measured at the time of accretion into the host halo, and normalized to the stellar mass of the primary at $z = 0$ (bottom panel). The shaded histogram corresponds to satellites that remain self-bound at $z = 0$; the other histogram corresponds to satellites that merge with the primary before $z = 0$. The curves in the top panel indicate the cumulative fraction of all *accreted stars* contributed by each of these two populations. Note that the “building blocks” of the stellar halo are significantly more massive than the average surviving satellite. On average, accretion events bring about 25% of the total number of stars into the primary, 40% of which remains attached to satellites until $z = 0$. The remainder belongs to “merged” satellites, the majority of which make up the stellar halo. The total number of stars contributed by disrupted satellites exceed those locked in surviving satellites by $\sim 50\%$.

$r_{\text{per}}/r_{\text{apo}}$ for merged and surviving satellites, respectively. Clearly, the eccentricity of the orbit is important for the chances of survival of a satellite: most satellites originally on very eccentric orbits have merged with the primary by $z = 0$, and the reverse is true for surviving satellites (see bottom panel in Figure 8).

Satellites that merge with the primary by $z = 0$ experience on average a more substantial circularization of their orbits; the median $r_{\text{per}}/r_{\text{apo}}$ evolves from 0.06 to roughly 0.15 in the time it takes their orbital energies to decrease by e^{-1} . Further circularization may be expected by the time that the satellite merges with the primary and, under the right circumstances, a satellite may even reach a nearly circular orbit before merging (see, e.g., Abadi et al 2003b, Meza et al 2005).

Orbital circularization has been proposed as an important factor to consider when interpreting the effects of satellite accretion events (although see Colpi et al 1999 for a different viewpoint). Abadi et al (2003b) argue, for example, that a satellite on a circularized orbit might have contributed a significant fraction of the thick-disk stars (and perhaps even some old thin-disk stars) of the Milky Way. A further example is provided by the “ring” of stars discovered by the SDSS in the anti-galactic center direction (Newberg et al. 2002; Yanny et al. 2003; Helmi et al. 2003), which has been successfully modeled as debris from the recent disruption of a satellite on a nearly circular orbit in the outskirts of the Galactic disk (Peñarrubia et al. 2006). Since it is unlikely that the satellite formed on such orbit (otherwise it would have been disrupted much

Figure 10. Accretion redshift distribution of surviving (bottom panel), merged (middle) and all (top) satellites in our simulations. All histograms are scaled to the total number of satellites for ease of comparison between panels. Dashed vertical lines indicate the (average) redshift where the primary galaxy has accreted 25%, 50% and 75% of its *total* mass at $z = 0$. In each panel the arrow shows the median satellite accretion redshift. The dotted curves trace the cumulative distribution of satellites (by number) as a function of z_{acc} (scale on right). Solid lines are like dotted ones, but by mass.

earlier) its orbit has probably evolved to become more bound and less eccentric as dynamical friction brought the satellite nearer the Galactic disk, in agreement with the trend shown in Figure 8.

3.6 Satellites and stellar halo: similarities and differences

The main result of the trends discussed in the preceding section is the obvious mass bias present in the population of surviving satellites: massive satellites merge too quickly to be fairly represented amongst satellites present at any given time. This is shown in the bottom panel of Figure 7; although the accretion of satellites with masses exceeding 10% of the host (at the time of accretion) is not unusual, few have survived self-bound until $z = 0$.

This is also true when expressed in terms of the total stellar mass that these accretion events have contributed to the simulated galaxy. As shown in Figure 9, merged satellites dominate the high-mass end of the distribution of accreted satellites, and make up on average $\sim 60\%$ of all accreted stars. Half of this contribution comes in just a few massive satellites exceeding 10% of the final mass in stars of the host (see upper panel in Figure 9). On the other hand, surviving satellites contribute on average $\sim 40\%$ of all accreted stars and have a combined stellar mass of about 12% of the host at $z = 0$. Half of them are contributed by satellites less than $\sim 3\%$ as massive as the host at $z = 0$.

Because of the strong orbital decay dependence on mass, surviving satellites are also biased relative to the overall population of accreted material in terms of accretion time. This is shown quantitatively in Figure 10, which shows the z_{acc} distribution for all

Figure 11. Mass fraction attached to surviving satellites at $z = 0$, shown as a function of radius, normalized to the virial radius of the host. The open circles are the results of the dark matter-only simulations of Gao et al. (2004), which are in very good agreement with ours. This figure shows that, although surviving satellites have lost a significant fraction of their dark mass to tides, their stellar components have survived almost unscathed. Overall, satellites inside the virial radius have conserved about 40% of their original dark mass, and $\sim 75\%$ of their stars. This suggests that stars stripped off surviving satellites are in general an unimportant contributor to the stellar halo, and highlights the need for simulations that include gas cooling and star formation to estimate the importance of tidal stripping in the satellite population.

satellites accreted since $z = 4$ (top panel). The bottom and middle panels, respectively, split this sample between satellites that have either survived or merged with the host by $z = 0$. The vertical lines in this figure illustrate the average mass accretion history of the hosts in our simulation series: from left to right, the vertical lines indicate the average redshift when the last 25%, 50%, and 75% of the mass were assembled into the virial radius of the host.

The accreted satellites, as a whole, trace very well this accretion history, as may be seen from the histogram in the top panel, or by the dotted line, which indicates the cumulative accretion history (scale on right). Just like the total mass, half of all satellites were accreted before $z \sim 1.8$ (see arrow labeled “50%”). The results are quite different for “merged satellites”; half of them were actually accreted before $z = 2.4$, which corresponds to a lookback time of ~ 2.7 Gyr. Essentially no satellite accreted after $z = 0.5$ has merged with the primary. Surviving satellites, on the other hand, are substantially biased towards late accretion. Half of them were only accreted after $z = 1.4$, and the last 25% since $z \sim 1$.

Since stars brought into the galaxy by merged satellites contribute predominantly to the stellar halo (see, e.g., Abadi et al 2006), this result shows convincingly that substantial differences must be expected between the stellar halo and surviving satellite population in a galaxy built hierarchically. *The “building blocks” of the stellar halo were on average more massive and were accreted and disrupted much earlier than the population of satellites that survive until the present.*

Our results provide strong support for the semianalytic mod-

eling results of Bullock & Johnston (2005). Despite the differences in modeling techniques (these authors use theoretical merger trees to simulate Monte Carlo accretion histories and a semianalytic approach to distinguish stars and dark matter within accreted satellites), our results agree well. For example, they find that $\sim 80\%$ of the stellar halo is contributed by the ~ 15 most massive disrupted satellites; we find, on average, 70%. The median accretion time for disrupted satellites is ~ 9 Gyr ago; we find ~ 10.5 Gyr. Lastly, they find that the median accretion time of surviving satellites was as recently as ~ 5 Gyr in the past; we find ~ 8.5 Gyr.

As discussed by Font et al. (2006a,b), these results may help to explain the differences between the abundance patterns of halo stars in the solar neighbourhood and in Galactic dwarfs (Fuhrmann 1998; Shetrone et al. 2001, 2003; Venn et al. 2004). Although stars in both the halo and satellites are metal-poor, the stellar halo is, at fixed $[\text{Fe}/\text{H}]$, more enhanced in α elements than stars in the dwarfs, suggesting that its star formation and enrichment proceeded more quickly and thoroughly than in Galactic satellites. This is qualitatively consistent with the biases in the surviving satellite population mentioned above. Because of the limited numerical resolution of our simulations and our inefficient feedback recipe, we are unable to follow accurately the metal enrichment of stars in our simulations. Although this precludes a more detailed quantitative comparison between simulations and observations, we regard the distinction between satellite and stellar halo reported here as certainly encouraging.

One final issue to consider is that, in principle, stars may also end up in the stellar halo as a result of partial stripping of surviving satellites. If substantial, this process might make stars in the stellar halo difficult to differentiate from those attached to satellites, despite the biases in mass and accretion time discussed above. As it turns out, stripping of surviving satellites adds an insignificant fraction of stars to the halo in our simulations; stars stripped from surviving satellites make up a small fraction ($\sim 6\%$) of all halo stars.

This is shown in Figure 11, where we plot the fraction of stars and dark matter that remains attached to surviving satellites as a function of the distance to the center of the galaxy. As shown by the filled triangles, more than 75% of the stars brought into the system by surviving satellites remain attached to them at $z = 0$. We conclude that the bulk of the halo population is not affected by stars stripped from existing satellites, and that the substantial difference between the stellar population of Galactic dwarfs and of the stellar halo predicted above is robust.

4 SUMMARY

We have analyzed the properties of satellite galaxies formed in a suite of eight N-body/gasdynamical simulations of galaxy formation in a Λ CDM universe. Our simulations are able to resolve, at $z = 0$, the ~ 10 most luminous satellites orbiting around $\sim L_*$ galaxies. We also track satellites that have merged with, or been disrupted fully by, the primary galaxy at earlier times, giving us a full picture of the contribution of accreted stars to the various dynamical components of the galaxy.

As discussed in an earlier paper of our group (Abadi et al 2006), the stellar halo consists of stars stripped from satellites that have been fully disrupted by the tidal field of the primary. Our analysis here focuses on the spatial distribution, kinematics, and merging history of the population of surviving and merged satellites, and

on their significance for the formation of the stellar halo. Our main results may be summarized as follows.

- The spatial distribution of satellites at $z = 0$ is consistent with that of the dark matter in the primary galaxy's halo, and is significantly more extended than the stellar halo. On average, half of the ~ 10 brightest satellites are found within $0.37 r_{\text{vir}}$, comparable to the half-mass radius of the dark matter component. The half-mass radius of the stellar halo is, on the other hand, only $0.05 r_{\text{vir}}$.

- The kinematics of the satellite population is also similar to the dark matter's. Satellite velocities are mildly anisotropic in the radial direction, with $\beta_{\text{sat}} \sim 0.3\text{--}0.4$, but not as extreme as stars in the halo, which are found to have $\beta_{\text{halo}} \sim 0.6\text{--}0.8$ in the outskirts of the system. Satellite velocity dispersions drop from the center outwards, and decrease by about a factor of two at the virial radius from their central value. Overall, the velocity dispersion of the satellite population is found to provide a reasonable estimate of the halo's virial velocity: $\sigma_{\text{sat}}/V_{\text{vir}} \sim 0.9 \pm 0.2$, where the uncertainty is the rms of the eight simulations.

- The orbits of satellites evolve strongly after accretion as a result of dynamical friction with the host halo and of mass stripping by tides. More massive satellites spiral in faster than less massive systems and are disrupted quickly as they merge with the primary, adding their stars mainly to the stellar halo. The orbits of satellites with masses exceeding 10% of the host mass decay on exponential timescales shorter than an orbital period, and merge shortly after accretion. Merged satellites typically make up $\sim 63\%$ of all accreted stars in a galaxy, a substantial fraction of which (57%) was contributed by these few most massive satellites.

- Surviving satellites are a substantially biased tracer of the whole population of stars accreted by a galaxy. In contrast with the "merged" satellites that build up the halo, surviving satellites are predominantly low-mass systems that have been accreted recently. Half of the stars in the stellar halo were accreted before $z \sim 2.2$, and were in satellites more massive than $\sim 6\%$ of the host at the time of accretion. In contrast, half of the stars in surviving satellites were brought into the system as recently as $z \sim 1.6$, and formed in systems with masses less than 3% of the host.

- Satellite orbits are continuously circularized by dynamical friction as they orbit within the primary's halo. The pericenter-to-apocenter ratio typically doubles once the orbital binding energy of the satellite has increased by a factor of e .

- Stars stripped from satellites that remain self-bound until the present make up an insignificant fraction of all stars accreted by a galaxy, showing that, once started, the disruption process of the stellar component of a satellite progresses on a very short timescale. Surviving satellites conserve at $z = 0$ about 75% of the stars they had at accretion time. Their surrounding dark halos, on the other hand, have been stripped of more than $\sim 40\%$ of their mass.

Our results offer a framework for interpreting observations of the satellite population around luminous galaxies and for extracting information regarding their dark matter halos. They also show that hierarchical galaxy formation models may explain naturally the differences in the properties of stars in the stellar halo and in Galactic satellites highlighted by recent observational work. Although our modeling of star formation is too simplistic (and our numerical resolution too poor) to allow for a closer, quantitative assessment of this issue, it is encouraging to see that, despite their differences, stellar halos and satellites may actually be both the result of the many accretion events that characterize galaxy formation in a hierarchically clustering universe.

ACKNOWLEDGEMENTS

LVS and MGA are grateful for the hospitality of the Max-Planck Institute for Astrophysics in Garching, Germany, where much of the work reported here was carried out. LVS thanks financial support from the Exchange of Astronomers Programme of the IAU and to the ALFA-LENAC network. JFN acknowledges support from Canada's NSERC, from the Leverhulme Trust, and from the Alexander von Humboldt Foundation, as well as useful discussions with Simon White, Alan McConnachie, and Jorge Peñarrubia. MS acknowledges support by the German Science foundation (DFG) under Grant STE 710/4-1. We thank Scott Chapman and collaborators for sharing their results on Andromeda XII in advance of publication. We also thanks to the referee Andrew Benson for useful suggestions and comments on this paper.
